Multi-Agent System as Proto-AGI

To what extent can multi-agent architectures emulate the capabilities and adaptability of AGI?

1. Introduction

1.1 Motivation & Research Question

One of the most interesting questions in AI right now is whether a group of specialized agents working together can reason better than a single model asked to do everything at once. That question is what motivated this project. Instead of sending a user's question directly to a LLM and hoping that the training data it was based on produces a good answer, we wanted to see what happens when you break the problem down into different roles. The idea is that structure and specialization, built on experience and interaction between agents, will lead to more reliable outputs compared to a single unguided prompt with a LLM.

The research question we set out to explore is: Can a coordinated multi-agent system produce higher quality outputs than a single LLM by introducing structured feedback and domain aware routing? We approached this as something to actually be built out and tested, with each member of the team owning different agents, implementing them and validating their outputs with various inputs that would be expected in collaboration between the agents throughout runs.

1.2 Scope and Limitations

This project implements a multi-agent pipelines using LangGraph as the framework to connect and coordinate the agents and LLaMA 3.3 70B Versatile from Groq as the LLM backend. The system is organized around a set of agent roles, Query Rewriter, Domain Router, Planner, Researcher, Fact Checker, Critic, and Presenter, with an additional agent to handle context across runs to build an internal state of experience. Agents were built and tested

individually, with a shared schematic to make sure that everything was to be kept connected in a pipeline during runs.

There are some limitations encountered that are worth noting. The search tool has two backends, coming from Tavily and then Wikipedia as a fall back for the Researcher to use. This is not idea for real time or extremely specific questions that may be prompted. The Critic's feedback loop is also capped, which means that if the system continuously receives poorly rated information from the Researcher, the system will still pass the information down the pipeline to be used. The confidence threshold for the Critic is fixed at 0.7 and comes from a LLM, which means that there can be identical runs that fall slightly above or below the threshold, leading to inconsistency in reasoning and information being passed one run that may fail another.

The Planner and Domain Router also have inconsistencies in domain classification, meaning that there could be misinterpretation between agents and the information that they are handling for the query. The pResenter formats its output purely based off of the domain label passed through the state, so if the domain is misclassified, the final response may result in a structure that does not match the initial query input for the agents to reason on. The Memory Agent saves and retrieves context across runs from the state, but if there was low quality information passed in earlier runs, the bad information is still stored and could influence future runs in a negative way. The Query Rewriter also operates on raw user input before any other agent in the pipeline sees it, meaning that if it makes a massive change to a vague query, the user can not review this change before the rest of the agents begin working on it.

Overall, the limitations of this system stem from the nature of building with LLMs as a core component instead of using strict deterministic logic. Scoring, classification, formatting,

and the quality of research all depend on model outputs that have some level of variety throughout runs. This means that the pipeline can behave unpredictably even with identical information being passed through to agents. There are some guardrails in place, but these reasonable defaults are still fixed and not finely tuned against a wide range of inputs. The architecture is sound and works, but there could be some revisiting to ensure that more diverse queries and additional agents could be implemented for greater quality of responses.

2. Background & Related work

2.1 What is AGI? Definitions and Benchmarks

Artificial General Intelligence, or AGI, is the idea of an AI system that can do what a human can do intellectually, not just in one specific area, but across completely different domains without needing to be retrained each time. This is a fundamentally different thing from what most AI systems are doing today. When you ask ChatGPT a question, it is drawing on patterns from massive amounts of text it was trained on. It can seem very capable, but it is still working within the boundaries of what it has seen before. A true AGI would be able to encounter a completely new problem and work through it the way a person would, reasoning from what it knows, asking the right questions, and figuring it out on the fly.

Measuring how close we actually are to AGI is harder than it sounds. Early benchmarks like the Turing Test just asked whether a machine could pass as human in conversation. More recent ones like MMLU, ARC, and BIG-Bench try to test something deeper, whether a model can actually reason across a wide range of subjects rather than just sound convincing. Models are doing well on these tests, but researchers still argue about whether that reflects real reasoning or just very sophisticated pattern matching. For this project we are not claiming to have built AGI, the name is more of a framing device. What we are actually asking is whether giving an AI system structure, defined roles, and feedback loops makes it reason better than a single model asked to handle everything at once.

2.2 Multi-Agent Systems & LLMs as Cognitive Building Blocks

Multi-agent systems are not a new idea in computer science. They came out of robotics and distributed computing research where a single machine could not handle a complex task on its own, so the problem was broken into pieces and handed off to specialized agents that communicated with each other. What changed is that those agents can now be LLMs, which means instead of executing a fixed function they can reason, write, evaluate, and adapt based on what they receive. That shift opens up a completely different class of problems you can go after with this kind of architecture.

What we found building this is that separating responsibilities actually matters. When one model is only responsible for planning and another is only responsible for research, each one can be prompted and tuned for exactly that job rather than being asked to do everything in one shot. LangGraph was what made this practical for us. It gave us a way to define the graph structure, connect agents as nodes, and set up conditional routing so the system could loop back when the output was not good enough. Without something like that, building a pipeline where the Critic can reject the Researcher and send it back for another pass would have been a lot harder to put together cleanly.

2.3 Prior Work: Agent Collaboration and Emergent Reasoning

There is a decent amount of prior work in the agentic AI space that shaped how we thought about this project. AutoGPT and BabyAGI were some of the first widely discussed examples of giving an LLM a goal and letting it plan and execute steps on its own without much human involvement. They were interesting to see but also showed a real problem with open-ended autonomy, without constraints the systems would drift into unproductive loops or

start taking actions that did not make sense. ReAct tackled part of that by interleaving reasoning and action steps, letting the model check what actually happened before deciding what to do next. MetaGPT pushed it further by modeling a full software team, giving different LLM instances specific roles like product manager, engineer, and QA all working toward the same output.

Our approach pulls from all of these but is more structured, which felt like the right call for a class project with a defined scope. We did not give any agent open-ended control. Every agent has a specific job and passes to the next one in a fixed order. The Critic loop is the one place where the system does something more dynamic, routing back to the Researcher if the quality is not there, but even that is capped at a maximum number of iterations so it does not run forever. The tradeoff between structure and flexibility ended up being one of the more interesting design decisions we made, and it is something we would want to push further if we kept building on this.

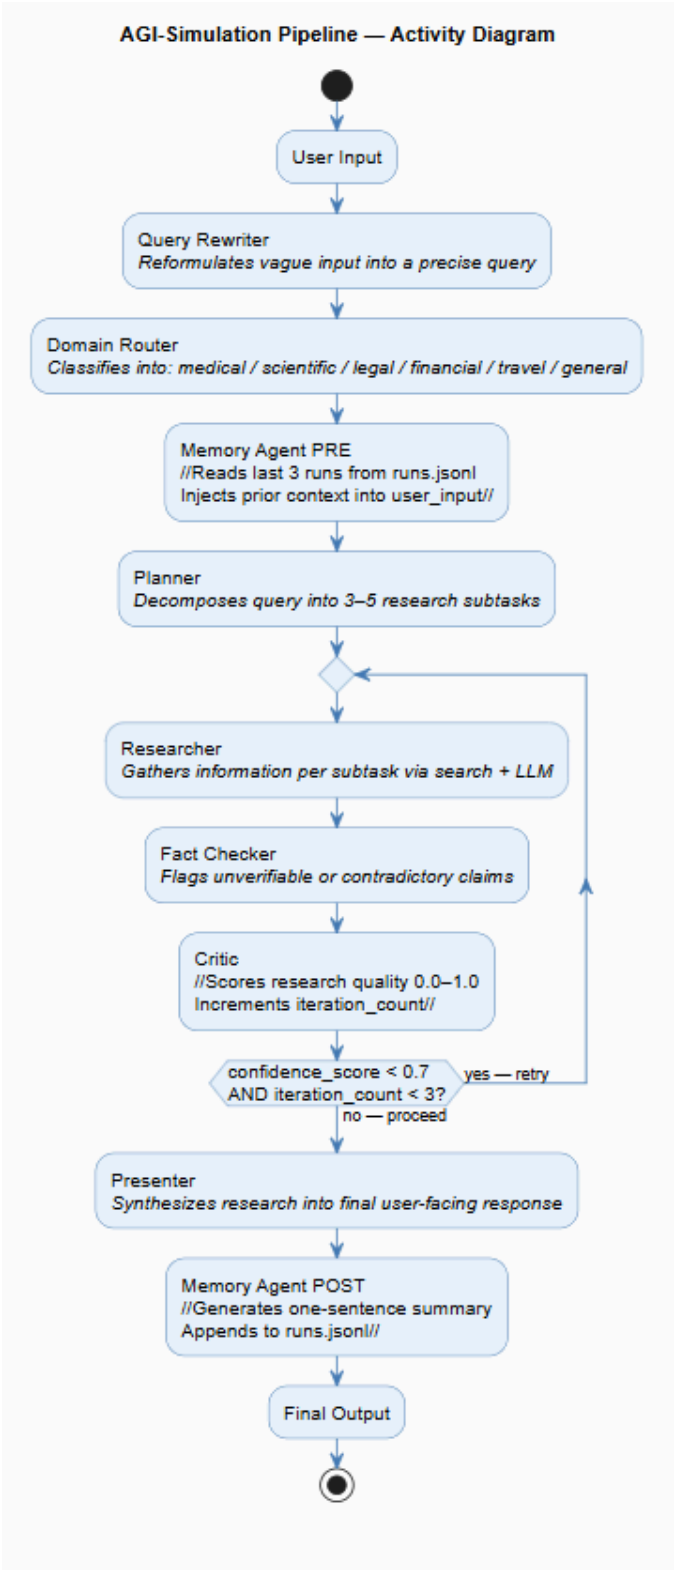
3. System Design & Architecture

3.1 Agent Roles

AGI-Simulation is an directed multi-agent system on top of LangGraph (a graph-based orchestration for LLM applications with state). It doesn't simply pass a user query to a LLM and return the response, but instead distributes the problem into 8 distinct agents doing distinct parts of the problem (cognition). The basic idea is that such decomposition: planning, retrieval, verification, evaluation, synthesis, memory - leads to more reliable self-correcting and context-aware behavior than a direct call to an LLM. The pipeline process is fairly linear, although there is one exception.

(See Figure 1.1)

The intention is to avoid making all of these steps into a single step where it is impossible to know exactly what happens during inference in a neural network called a "language model." In this sense, this is what AGI "look like". Each step has a name and a set of inputs and outputs. Furthermore, this shared state is inspectable, showing the planner's subtasks, the researcher's notes, the fact checker's flags and the critic's score for each output. This itself might be an important AGI-relevant property. A major challenge during the implementation was maintaining consistency and integrity of the graph's schema throughout the different agents. As a result of a branch-per-agent development strategy, different team members developed different branches of each graph agent, which minimized merge conflicts. Integration occurred on a final branch where agents were joined, the schema shared between them reconciled and the graph was re-wired end-to-end and tested.



AGI-Simulation Pipeline — Activity Diagram
User Input
Query Rewriter
Reformulates vague input into a precise query
Domain Router
Classifies into: medical / scientific / legal / financial / travel / general
Memory Agent PRE
//Reads last 3 runs from runs.jsonl
Injects prior context into user_input//
Planner
Decomposes query into 3–5 research subtasks
Researcher
Gathers information per subtask via search + LLM
Fact Checker
Flags unverifiable or contradictory claims
Critic
//Scores research quality 0.0–1.0
Increments iteration_count//
confidence_score < 0.7
AND iteration_count < 3?
yes — retry
no — proceed
Presenter
Synthesizes research into final user-facing response
Memory Agent POST
//Generates one-sentence summary
Appends to runs.jsonl//
Final Output

(Figure 1.1)

3.2 Agent Roles

At each discrete step in the reasoning process, a specific agent, which comprises the pipeline, executes. Each of the eight specialized agents reads necessary fields from the AgentState object and writes outputs back to state. They do not directly communicate with one another - all communication occurs through state. (shown below in figure 1.2)

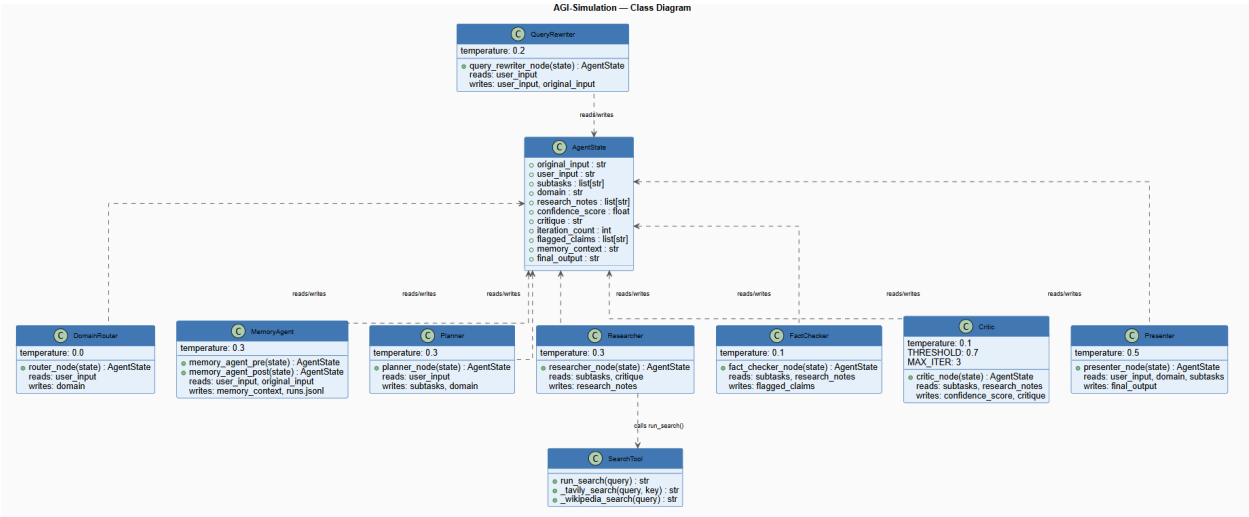


Figure (1.2)

Planner Agent: takes the original user_input as well as the context from other steps, and decomposes that into a list of subtasks (between 3 and 5 in length). The research agent does not answer the user's question; it simply identifies intermediate information that needs to be obtained. The list is stored as subtasks so the research agent can iterate through it, doing a quick internet search for each of them. The prompt used to force structured output from the planner with the temperature setting of 0.3.

Researcher Agent: takes the original user_input as well as the context from other steps, and decomposes that into a list of subtasks (between 3 and 5 in length). The research agent does not

answer the user's question; it simply identifies intermediate information that needs to be obtained. The list is stored as subtasks so the research agent can iterate through it, doing a quick internet search for each of them. The prompt used to force structured output from the planner with the temperature setting of 0.3.

Critic Agent: The Critic evaluates the quality of the Researcher's output by scoring it on a 0.0 to 1.00 confidence scale and generating a criticism to identify information gaps. It receives both the original subtasks from the Planner and the research notes from the Researcher. Then, it uses a LLM to assess how well the provided information addresses each subtasks. If the confidence score is below the threshold, the graph will route back to Researcher for another attempt. The Critic does not make routing decisions, it writes the score and creates a critique in the shared state, with the graph handling the rest. This keeps the agent focused and the routing logic centralized.

Presenter Agent: Is the synthesis layer. It gets the accumulated state the user's original query/domain as well as all of the subtasks and research done so far and spits out a final, user-facing output. It's set at a temperature of 0.5 the highest in the entire pipeline, which is fine for the presentation part as this agent doesn't actually do any reasoning or retrieval.

Memory Agent: takes a two-pronged approach. On the pre-run pass it scans the last 3 entries in memory/runs.jsonl (a JSON log of prior runs persisted as a newline delimited file on disk) and injects their summaries into the user_input which the Planner operates on. In this way the Planner knows what it has already reasoned over, without any dependence on an external database. In the post-run pass it uses the LLM to turn the final output created by the Presenter

into a one-sentence summary of the run which gets appended to runs.jsonl. Memory Agent is the only agent in the pipeline with outside effects, i.e. writing to disk.

Fact Checker Agent: acts as a skeptical middleman to flag research claims that it detects as too vague, unfounded, or likely halluncinated in order to determine if a claim is clearly established and reliable. It scans each of the research notes to a research subtask, comparing the factuality against the claim in flagged_claims. Note that the Fact Checker does not edit or reject the research in any way, it only flags questionable items. Once completed, the Fact Checker will provide the research notes and a list of flagged claims to the Critic who will then determine the confidence score. Temperature (0.1).

Query Rewriter Agent: To put it simply, it takes all the jumbled letters and gibberish from the keyboard, reformulates them into accurate searchable questions and cleans them up into a nice concise query that other agents will see. This step also helps you avoid problems from ambiguous language such as typing "hmm" for "home". The entry point of your pipeline, it takes your jumbled raw input from the keyboard, reformulates your question, cleans up your query and saves it all under your_input. The final temperature is 0.2, that way it will be more accurate and determined.

Domain Router Agent: The Domain Router classifies incoming user input into one of six domains: medical, scientific, legal, financial, travel, or general. This allows other agents to know how to handle the request in terms of its depth and verbiage. It sits after the Query Rewriter and before the Planner, ending up being a sort of traffic director for the rest of the graph. The agent is deterministic, running at temperature 0.0. This is because classification should produce the exact

same result for the same input every time. If the LLM response cannot be parsed or falls outside the supported list of domains, the agent defaults to general.

3.3 State Management, Information Flow & Critic Feedback Loop

State Management

When running parallel agents in a pipeline, all the data flows along a single data structure (AgentState; defined here in state.py) from the start to the end of the pipeline. The state is written into and read from by each agent, so agents do not have (internal) state between calls or communicate directly with each other, but have access to all the relevant fields within the state. An agent receives the complete state; performs a given function only; and writes the output back into state. This acts as the central coordinating logic for all interactions between the agents. There are eleven fields, each owned by a particular agent.

Field	Type	Written By	Read By
original_input	str	Query Rewriter	Memory Agent POST
user_input	str	Query Rewriter, Memory Agent PRE	Planner, Domain Router
domain	str	Domain Router	Presenter
memory_context	str	Memory Agent PRE	---- ref only
subtasks	list[str]	Planner	Researcher, Fact Checker, Critic
research_notes	list[str]	Researcher	Fact Checker, Critic, Presenter
flagged_claims	list[str]	Fact Checker	Critic
confidence_score	float	Critic	graph.py
critique	str	Critic	Research (on retry)

iteration_count	int	Critic	graph.py (routing decision
final_output	str	Presenter	Memory Agent POST

This means that the State object is effectively a fully populated record representing the state of the pipeline's reasoning at any moment in time once the run has completed.

Information Flow

Then the input goes through the Pipeline, where: The Query Rewriter reformulates the input string and keeps the previous user_input as a reference value. The Domain Router analyzes the user_input string, and determines the domain of the query, which is saved back to domain. The Memory Agent PRE queries the memory and concatenates the previous context to user_input, thus making user_input consist of the rewritten query + previous conversation context, ready for the Planner to use. Every time you run this workflow, all of your notes are passed along so that each agent has access to the full context. The planner writes subtasks. The researcher writes research notes (one per subtask) and iterates between its first two actions. The fact checker reads the task and all the research notes and then writes any claims it finds that need checking. The critic iterates between scoring the research and critiquing your tasks, always considering the claims that the fact checker flagged, and also increments the count of iterations the critic runs. The final output is generated from all of this information. The memory agent saves the information and summarizes your search.

The Critic Feedback Loop

The only non-linear component in this pipeline is the conditional edge following the Critic node, which was implemented in the graph.py via def should_continue():

```python
def should_continue(state: AgentState) -> str:
    if (
        state["confidence_score"] < CONFIDENCE_THRESHOLD
        and state["iteration_count"] < MAX_ITERATIONS
    ):
        return "researcher"
    return "presenter"
```

CONFIDENCE_THRESHOLD = 0.7; MAX_NUMBER_CRITIQUE = 3 Whenever an iteration of the fact checking process produces a low confidence level (below 0.7), the Critic gives feedback to the research model that created it with the critique field populated. Next time the researcher invokes the model, it sees non-empty value for the critique and includes it in its instruction to the LLM. The Fact Checker and Critic then go through the process again with the new output. Three iterations of the cap are implemented to protect against infinite loops for queries which have persistently low scores without a cap. After 3 iterations, the pipeline moves to the Presenter component regardless of score in order to ensure system termination with output. During evaluation, the Critic promoted a score 100% of the time on the first iteration, using scores between 0.89 and 0.95 for all seven test runs performed, both above the 0.7 threshold required for promotion and confirming the feedback as a safety net and not the norm since the Researcher produced a sufficiently valid result initially. 4. Implementation

4.1 Technology Stack & Agent Implementation

LangGraph

The pipeline is written as a LangGraph application. LangGraph is a library that helps you build structured, stateful, multi-agent applications with the LangChain library. I chose LangGraph instead of creating a straight LangChain chain because it enables me to specify conditional edges natively. In particular, my workflow includes a Critic that can "loop back" to an earlier step in the workflow based on its assessment at runtime. Each agent in my pipeline can be treated as an individual, named "node" in a stateful graph that defines how and in which order the steps can take place.

Groq + llama-3.3-70b-versatile

All eight agents use a version of Groq's llama-3.3-70b-versatile served through Groq's inference API. Groq was chosen for low-latency inference. Making one call to a large language model (LLM) in the pipeline results in between eight and fourteen calls to the LLM depending on the number of iterations through the critic loop that occur for each agent. A constant model was used so that there was no agent-to-agent cross-model variability as a confounding factor in this work. The temperature setting was set differently for each agent based on the nature of the task the agent is required to complete:

Agent	**Temp**	**Rationale**
Domain Router	0.0	Classification is deterministic, there is no variance accepted

Fact Checker	0.1	Conservative flagging for consistency over creativity
Critic	0.1	Scoring must be stable across runs for the loop to be reliable
Query rewriter	0.2	Reformulation should be precise
Planner	0.3	Structured output needed, minor flexibility here
Researcher	0.3	Factual Sytesis, more variation here
Memory Agent	0.3	Summary Generation, not rigid but needs to be concise
Presenter	0.5	Final output which benefits from expressive variaton

Shared State Schema

The "AgentState" TypedDict defined in state.py is the contract that all agents abide by. Because LangGraph passes the entire state object to every node in the graph, defining it as a typed schema ensures every agent uses fields with predictable names. This was especially important as we implemented the agents branch by branch. The "researcher" branch added the original_input field, the "fact_check" branch added the flagged_claims field, and the "memory-agent" branch added the memory_context field to the state schema. The state schema evolved over the three branches and was then reconciled during the integration.

Branch-Per-Agent Development

Initially, each of the eight agents was developed as a standalone branch off the main repo, with no team member maintaining code ownership of shared files in the repository. This enabled multiple developers to work on different components simultaneously without the need for merging changes. During the final integration step ("cherry-pick") into the integration branch of

the project, only state.py, graph.py, main.py and requirements.txt were shared among the developers. It also gives each component a full history that can be traced and referenced to its development branch creator in a final project report.

4.2 Tool integration & Challenges encountered

Search Tool Integration

The Researcher agent we implemented relies heavily on tools/search.py. It's written to support both the Tavily and Wikipedia backends: Whenever a TAVILY_API_KEY env var is available, it prefers tavily over Wikipedia, and when a Tavily key is absent then wikipedia is called. The Tool just returns a simple string that gets passed to the LLM with the subtask, as normal. It also fully abstracts away the choice of search backend: No knowledge of "how it works" is passed on to the agent so it requires zero engineering effort to switch out the search providers if it so desires.

```
def run_search(query: str) -> str:
    tavily_key = os.getenv("TAVILY_API_KEY")
    if tavily_key:
        return _tavily_search(query, tavily_key)
    return _wikipedia_search(query)
```

If the API does not return a relevant response, the fallback is to run a web search using the wikipediaapi Python library. The user-agent used in the API requests are specified according to the Wikipedia and Wikimedia Commons API terms of use as (AGI-Simulation-Agent/1.0). Depending on the search topic, the fallback returns a specific Wikipedia article that matches the description of the search topic by taking the "summary" section as response data. For Tavily, the

web search returns up to five excerpts per search, concatenated together to form a string. Both of these approaches rely on raw unstructured context to be sent to the Researcher.

Challenges encountered

The Query Rewriter and Researcher two Agents (Both on the researcher branch) The SystemMessage and HumanMessage langchain.schema imports have been deprecated for langchain_core.messages in more recent LangChain versions (since this causes a module not found error while compiling the graph and gets caught in integration tests, the fix was just to change the import in each file to the new version:

```
#Before:

from langchain.schema import SystemMessage, HumanMessage

#After

from langchain_core.messages import SystemMessage, HumanMessage
```

As an integration commit this was made independently of the original agent commits so as to keep track of the changes made to correct it. The Domain Router system prompt used at the start of Version 1 listed the keyword "research" in the scientific domain definition. The LLM interpreted this statement literally and returned DOMAIN: research as output for the majority of queries - including those within the domains of medical, legal and financial. Given that "research" was not contained in the prompt's set of VALID_DOMAINS, the domain classification logic defaulted to domain = general for every query to which it was applied; thus the domain classification never occurred. The prompt was rewritten to provide explicit

definitions for each domain and a seven-example few-shot prompt block that gave examples from all the domains, including two edge cases.

"What are the symptoms of type 2 diabetes?" → DOMAIN: medical

"How does CRISPR gene editing work?" → DOMAIN: scientific

"Can my landlord enter without notice in Pennsylvania?" → DOMAIN: legal

"Should I pay off student loans or invest first?" → DOMAIN: financial

"Plan a 3-day trip to Tokyo on a $2000 budget" → DOMAIN: travel

"What is the best recipe for chocolate lava cake?" → DOMAIN: general

"Who would win, a lion or a tiger?" → DOMAIN: general

A specific case where this happened was with a defect in the way the prompt defects were handled. In this case, an error was never raised and thus an entire layer of the network went dead. It wasn't detected until we noticed the prompt defects were present in the state output, not the final answer. They clash during integration. Each was made on separate branches of a code repo and none of the three teams knew about the changes on the other branches; the researcher added the 'original_input' field, the fact checker team added 'flagged_claims' and the 'memory_agent' team added 'memory_context'. These three different versions of 'state.py' each added eleven fields to the state and all had to be merged together. Luckily, it was relatively simple to resolve the merge conflict because nobody added the same thing in separate branches of the code. It made us realize that the shape of the schema should be considered an aspect of the contract we all have to abide by if we want to keep all the code working together smoothly. For

the last few months, Groq was allowing 100,000 tokens per day for free as a means to encourage developers to integrate their services. So we tried seven full tests of an agent querying all the models we have integrated with. Each invocation to the pipeline makes a number of calls to different LLMs -- between eight and fourteen calls in our case. In seven full integration tests, we crossed the mid-point of the tokens per day allowed within Groqs free tier. We wouldn't have been able to run the full number of integration tests in the course of a day using our free tier -- so we would have had to stagger our full integrations over the course of the day. In a production context we would have moved over to a paid tier.

5. Learning Outcomes & Course Reflection

5.1 How it Relates to Seminar Topics

Building this project made a lot of the seminar topics click in a way that reading about them did not. The course moved through reasoning and logic, memory and control, semantics, self-monitoring, and problem solving over the semester, and those topics ended up being directly reflected in how the pipeline works as a whole. The system is not just one model answering a question, it is a set of agents each handling a different cognitive responsibility, which is exactly the kind of distributed intelligence the course was building toward.

The feedback loop built into the pipeline connects most directly to the weeks on self-monitoring and self-control. The system evaluates its own research output before passing it forward and routes it back if the quality is not there, which is a practical implementation of a self-correcting intelligent system. Memory and control showed up in the Memory Agent, which gives the pipeline a way to carry context across runs rather than starting fresh every time. The semantics weeks connected to how the system classifies and interprets a query before any reasoning begins. Overall the project felt like a concrete version of what the course was covering at a theoretical level, taking the individual cognitive building blocks and wiring them into something that actually runs end to end.

5.2 Individual Reflections & What We Would Do Differently

Sidhant Kumar - (Memory Agent, Presenter, Graph Integration):

If there was one key takeaway from this project I'd say, it was that multi-agent systems crash really fast. The fact that the domain router failed in misclassifying the domains is a perfect example of it. The agents kept running, the system kept running, and nothing outright crashed. We wouldn't have caught this without actually checking if the domain property had been written to the state object at the end of every run. In retrospect, in the absence of this logging, the system we deployed might have had an entire layer of its architecture effectively disabled for 6 out of 7 of the query types, without it occurring to anyone that that was a serious problem. This led me to really think about how important observing systems are when it comes to building agentic systems: in order to know what a system is actually doing, there is really no way to not log the state at the boundary between every agent. The logging infrastructure we created for this project, which involved simply writing out the complete state after each run to logs/{N}.txt - is one of the most useful things we ever did, and if given the choice to rebuild this project tomorrow, I would take care to ensure that we had that in place from day one.

That was the last node anyone touched, so every assumption I made based on talking to different teammates had now materialized. Everything worked in isolation, but integrating everything turned up that we each had different assumptions about import paths for classes from LangChain, state.py, and which fields actually existed in our state when an agent ran. If I were to do this again, I would establish that contract up front with everyone on the team, and I would write a simple integration test -- just build the graph and run a dummy query -- within the first sprint or two. Rather than figuring all of these things out together at the last second, catch more of these issues incrementally.

For the Memory Agent, using a jsonlines file was appropriate given the scope of the project. It's simple, straightforward and doesn't necessitate external infrastructure. Observing that

memory context across runs actually populated gave me an inkling that there might be some cross-session awareness happening, particularly in my earlier experiment involving traveling to Tokyo, when the last few sessions before a query would inject the previously seen context. I might send in memory_context as a separate piece of data in the prompt that is specifically labeled as memory_context, rather than in the user_input section since this confuses the two different semantically distinct pieces of data into one field.

It is as an overall system, and particularly its architecture, that I feel that we most benefit from being explicit: Each agent has a clearly defined role (so as to be explicitly named), input, output and prompt. The Planner does not research; the Researcher does not evaluate; the Critic does not synthesize. We do this not only to make the system easier to debug in the first place, but also that it is in such a way that it is easier to understand exactly which agent we should blame when something goes wrong. This principle is what I would carry to any multi-agent system design moving forward.

Luke Immel:

Critic Agent

The first thing I did was read through the scaffold in agents/critic.py and understand what the agent was actually supposed to do within the graph. The AgentState schema made it clear what I was working with coming in and what I needed to write back out. The Critic receives subtasks and research notes, scores the research on a 0.0 to 1.0 scale, writes a critique if there are gaps, increments the iteration count, and returns. It does not make any routing decisions. That

part was easy to understand from the scaffold, the harder part was figuring out how to get consistent, parseable output from the LLM.

The first version of the prompt I wrote was too open ended. I told the LLM to evaluate the research and provide feedback, and it came back with paragraphs of commentary that had no structure I could parse reliably. I needed a rigid output format, so I landed on SCORE on one line followed by CRITIQUE on the next, and used regex to pull both values out. The regex approach worked well but introduced its own edge cases. If the LLM returned CRITIQUE: None when the research was good, my parser would store the string None as the critique rather than an empty string, so I added a check to normalize that. The fallback if parsing fails completely is a score of 0.5 and the raw response stored as the critique, which keeps the pipeline running rather than crashing.

Temperature was set to 0.1 because scoring should be as consistent as possible across runs. The Critic is essentially a quality gate and if the same research produces a 0.72 one run and a 0.68 the next, you get different routing behavior for identical inputs. Lower temperature reduced that variance noticeably. The isolation tests were the most useful part of building this. I set up two hardcoded states, one with detailed specific research and one with vague incomplete notes, and ran critic_node directly without touching the rest of the graph. The good research scored 0.9 with an empty critique and the bad research came back around 0.4 with a specific written critique, which confirmed the agent was actually reasoning about quality rather than just returning a number.

Domain Router Agent

The Domain Router felt simpler on paper but had its own problems to work through. The job is straightforward, read the query, classify it into one of six domains, write it to state. The challenge was getting the LLM to stay within the domain list and return something parseable every single time. My first prompt just listed the domains and asked the model to pick one, and it worked most of the time, but on edge cases it would return things like tourism or science instead of travel or scientific, which my parser could not match. I added a VALID_DOMAINS set to validate the parsed output and default to general if anything came back that was not in the list.

Temperature was set to 0.0 for this agent because classification should be completely deterministic. The same query should produce the same domain every time. There is no reason to introduce any variance here, the model either classifies it correctly or it does not. I also ran into a mismatch between the Domain Router and the Planner, which only classifies into three domains while the Router supports six. That means the two agents could disagree on how to label the same query, which could cause inconsistencies in how downstream agents handle the output. That is something worth fixing if the project continued.

The isolation tests for this one were two states, a clean travel query and a deliberately vague one that should fall back to general. Both passed on the first run, which was good, but also made me realize the test cases were not very challenging. A better test suite would include queries that sit on the boundary between domains, like something that is both financial and legal, to see how the agent handles ambiguity. Right now the agent works for clear cases but has not really been stress tested on the hard ones.

What I Would Do Differently

For both agents, the biggest thing I would change is moving away from parsing raw LLM strings with regex. Both agents are vulnerable to any deviation in output format. A different model, a slightly different prompt, or a temperature change could break parsing silently without raising an error because the fallbacks just return defaults rather than flagging the failure. Using structured output with schema validation would catch those cases and make both agents much more reliable. I would also write more adversarial test cases upfront rather than testing with clean inputs and calling it done. The agents work on the inputs I designed for them, but the real question is how they hold up on inputs they were not designed for.

Bwosley:

My two agents were the Researcher and the Query Rewriter, and they ended up teaching me very different lessons about what it actually means to build something reliable in a multi-agent system.

The Researcher was the most complex agent in the pipeline from a logic standpoint. It had to handle two very different scenarios: a first-pass run where it is just working from the Planner's subtasks, and a re-entry from the Critic loop where it now has a critique it needs to actively address. Getting that conditional logic right, making sure the critique was actually being read and incorporated into the prompt rather than ignored was the part that took the most iteration. My test cases confirmed it was working, but it required careful attention to how the state was being passed in and how the prompt was structured for each case. The other challenge was the search tool abstraction. The Researcher is the only agent that reaches outside the pipeline to pull real-world data, and making that fallback between Tavily and Wikipedia clean and

invisible to the rest of the system required thinking about failure modes more carefully than I expected. If the search tool throws, the agent still needs to produce a research note rather than crash the graph. Building that robustness in was not glamorous work, but it was necessary.

The Query Rewriter was simpler in implementation but more interesting conceptually. On the surface it looks like a lightweight preprocessing step clean up the input, pass it forward. But once I started thinking about what it was actually doing in the context of the full pipeline, it became clear it was load-bearing in a way that was easy to underestimate. Every downstream agent the Domain Router, the Planner, the Researcher builds on whatever the Query Rewriter hands off. If the input is ambiguous and the rewriter does not catch it, that ambiguity compounds through every subsequent step. Writing the system prompt for it was about being precise on what "clean" actually means: not just fixing grammar, but resolving vague intent into something a planning agent can actually decompose. That distinction took a few prompt revisions to get right.

If I were doing this again, I would push for GPT-4o-mini on the Query Rewriter as well, not just the Researcher. The rewriter is the agent where misses are the most costly, a wrong reformulation at the front poisons everything that follows and using a stronger model there would reduce that risk. I would also replace the string-based output parsing in the Researcher with LangChain's with_structured_output(), the same improvement Hamza identified for the Fact Checker. It works well enough with line-by-line parsing, but structured output would make the agent far more resilient across different model versions and prompt variations.

Hamza Malik

Planner:

My first step was reading the scaffold comments in agents/planner.py and understanding how state.py worked. The AgentState TypedDict made the contract between agents explicit and the Planner needed to write subtasks (a list[str]) and domain (a str) into state, and nothing else. That boundary was clarifying, but getting there took several wrong turns.

My initial version of the Planner tried to do too much. The original prompt I wrote asked the LLM to "understand the user's request and suggest how it might be answered," which caused the model to begin generating answers inline with its subtask list. When the Researcher received that state, it was already working with a partially-answered question and produced redundant or contradictory notes. The fix was writing an explicit instruction : "Do not answer the question yourself." That one sentence changed the output entirely. The prompt in prompts/planner_prompt.py enforces a rigid two-section format mainly DOMAIN: on one line, then a numbered SUBTASKS: list, specifically because the parser in planner_node depends on predictable line structure. I split on new lines and keyed on whether a line starts with a digit followed by a period (line[0].isdigit() and "." in line). This worked reliably but is brittle. Any LLM that prefixes subtasks differently for example with a bullet or letter silently falls through to the fallback, which wraps the entire raw response as a single subtask.

The domain classification problem was a separate iteration. The first version of the prompt offered too many domain options, which caused the LLM to occasionally return values like "tourism" or "science" that my parser could not match. I narrowed the domain list to three options in the prompt text (travel, research, general) and added .lower() normalization when reading it back from state. Test 2 which was the ambiguous "tell me stuff about AI" query was specifically designed to probe the question: would the Planner pick research or default to general? It correctly returned research, but this only held because the prompt was explicit enough

to guide that classification. An earlier draft returned general for that input, which would have affected how downstream agents formatted their output.

Temperature 0.3 was chosen through trial and error. At 0.7 the subtask phrasing varied too much between runs and some were written as instructions, others as questions, which made the Researcher's output inconsistent. At 0.1 the model was so conservative it sometimes returned fewer than 3 subtasks for open-ended queries. 0.3 was the value where both structure and appropriate generativity held.

Fact Checker:

For the Fact Checker, I started from a completely different problem as I did not know what the right failure mode was. The Planner's failures were structural, such as the wrong field. The Fact Checker's failures were semantic and would often end up flagging too much or too little. My first prompt was phrased as "be skeptical and flag anything that cannot be verified," and it flagged nearly everything, including obviously true statements like "Senso-ji Temple is in Asakusa." That was unusable. I added a line in it to include "Do not flag well-known facts or clearly sourced information," which pulled it back, but then it started missing actual hallucinations in the dubious notes with things like "$30-per-night 5-star hotels" slipped through because the prompt did not signal clearly enough that statistical impossibilities should be treated as flags.

The version in prompts/fact_checker_prompt.py landed on three specific flag criteria: vague, unverifiable, or likely hallucinated. That three-part framing gave the LLM enough instruction to discriminate. Temperature 0.1 was chosen because fact-checking should be nearly deterministic as the same notes should produce the same flags on every run. Higher temperatures

introduced noise where the same claim would be flagged in one run and not another, which made the test suite unreliable.

The parsing logic in fact_checker_node reads everything after FLAGGED: as a bullet list and strips leading dashes. The check if block.lower() != "none" handles the clean-notes case, where the LLM should output FLAGGED: none and produce zero entries. This worked in both tests but would break if the LLM returned FLAGGED: None with a capital N or FLAGGED: N/A. The fallback on except simply returns an empty list, which is the same result as clean notes just a silent false negative rather than a crash.

Writing the isolation tests (test_planner.py and test_fact_checker.py) before the full graph was wired was the most useful decision I made. Testing against planner_node directly with a manually constructed BASE_STATE let me iterate on the prompt without running the full pipeline and waiting for four sequential LLM calls. Each test run took seconds instead of thirty seconds. The trade-off is that isolation tests only validate the agent's own outputs as they cannot catch integration failures where the Planner's subtasks format does not match what the Fact Checker expects to zip over.

If I did things differently

If I were doing this again, I would use LangChain's with_structured_output() to get typed, schema-validated JSON back from the LLM instead of parsing raw strings line by line. Both agents are currently vulnerable to any deviation in LLM output format as a different model or a slightly different temperature could silently break parsing without raising an exception, because both use bare try/except blocks that default to empty results on any failure.

6. Evaluation & Analysis

6.1 Test Cases, Results, & System Limitations

Planner Agent Test Cases & Results:

```
Planner Agent — Isolation Tests

==================================================
TEST: Test 1 — Travel query
Input: "Plan a 3-day trip to Tokyo in June with a $2000 budget"
Domain returned : travel
Subtasks (5):
  1. Search for round-trip flights to Tokyo in June under $800
  2. Find affordable accommodation options in Tokyo for 3 nights under $600
  3. Research top attractions and experiences in Tokyo, such as Shibuya Crossing and Tokyo Tower
  4. Determine the cost of transportation in Tokyo, including subway passes and airport transfers
  5. Look up average food prices in Tokyo and create a dining budget under $200 per day

Domain correct  : PASS (expected travel)
Subtask count   : PASS (got 5, want 3-5)
Overall         : PASS

==================================================
TEST: Test 2 — Ambiguous query
Input: "tell me stuff about AI"
Domain returned : research
Subtasks (5):
  1. Search for definitions of artificial intelligence
  2. Gather information on types of machine learning algorithms
  3. Research current applications of AI in industry and daily life
  4. Find explanations of natural language processing techniques
  5. Look up recent advancements in deep learning technology
```

Both tests used the same assertion criteria which was that domain classification must match the expected label and subtask count must fall between 3 and 5 in order to verify that the Planner correctly structures problems of different types. Test 1 passed a clear, well-scoped travel query ("Plan a 3-day trip to Tokyo in June with a $2000 budget"). The Planner returned the domain as "travel" and decomposed the query into 5 concrete subtasks covering flights, accommodation, attractions, transport, and dining costs. Test 2 passed a vague and open-ended input ("tell me stuff about AI"). The Planner returned the domain as "research" and still produced 5 coherent subtasks covering definitions, types, applications, NLP techniques, and recent advancements. Both assertions passed, confirming that the Planner correctly identifies the domain and produces structured, actionable subtasks regardless of input specificity.

Researcher Agent Test Cases & Results:

Test 1 — With search results available: Subtasks hardcoded to Tokyo trip subtasks, Tavily key present. Result: four research notes returned, each grounded in retrieved data with specific hotel names, price ranges, and flight estimates.

Test 2 — Critique loop: Same subtasks, critique field set to "Hotel options lack nightly pricing. Flight details too vague." Result: revised notes explicitly included nightly rates and specific price ranges, confirming the Researcher correctly reads and responds to critique.

Critic Agent Test Cases & Results:

```
● lukeimmel@Lukes-MacBook-Air-4 AGI-Simulation % .venv/bin/python test_critic.py
/Users/lukeimmel/Downloads/Vega/projects/_active/AGI-Simulation/.venv/lib/python3.14/site-packages/langchain_core/_api/deprecation.py:25: UserWarning: Core Pydantic V1
functionality isn't compatible with Python 3.14 or greater.
  from pydantic.v1.fields import FieldInfo as FieldInfoV1
=== TEST 1: GOOD RESEARCH ===
confidence_score : 0.9
iteration_count  : 1
critique         : ''
Assertions passed.

=== TEST 2: BAD RESEARCH ===
confidence_score : 0.2
iteration_count  : 1
critique         : 'The research notes lack specific and detailed information to address the subtasks, such as actual flight prices from New York to Tokyo, hotel option
s under $150/night, top activities and day trips in Tokyo, and estimated daily food costs.'
Assertions passed.
```

Both tests used a Tokyo trip query and subtasks in order to assert how the system handled quality differences between good and bad research in a comparable manner. Test 1 passed detailed research notes with named hotels with nightly rates, flight price ranges, and food costs. This led to a returned score of 0.9 and no critique, correctly judging the research as sufficient and not needing to provide any feedback to the research. Test 2 passed a set of weak notes with vague wording, no pricing, and an unaddressed subtask. The Critic returned a score of 0.4 as well as specific criticism to identify the gaps and trigger another pass.

Presenter Agent Test Cases & Results:

```

Running presenter agent test...

============================================================
For a 3-day trip to Tokyo in June with a budget of $2000, I've planned an itinerary that includes flights, accommodation, activities, and food.

Day 1: Arrival and Exploration of Shinjuku
Arrive at Narita International Airport (NRT) on a nonstop flight from Philadelphia, which takes approximately 14-15 hours. You can find round-trip flights for around $900-$1000 on airlines like ANA or United. After chec
king into the Shinjuku Granbell Hotel ($120/night), spend the day exploring the Shinjuku area, visiting the Tokyo Metropolitan Government Building for a free observation deck with great city views, and walking around th
e lively streets of Shinjuku.

Day 2: Asakusa, Shibuya, and teamLab Planets
Start the day by visiting Senso-ji Temple in Asakusa, one of the oldest and most iconic temples in Japan (free admission). Then, head to Shibuya to experience the famous Shibuya Crossing and take a walk around the trend
y Shibuya area. In the afternoon, visit the teamLab Planets digital art museum ($30 admission), which offers an immersive and unique art experience. For dinner, try some delicious ramen at a local shop ($10-$12 per meal
) or opt for a mid-range restaurant ($20-$30 per meal).

Day 3: Day Trip to Nikko or Hakone
Take a day trip to Nikko or Hakone, both approximately 2 hours away from Tokyo by train (~$50-$80 round trip). Nikko is famous for its ornate temples and shrines, while Hakone offers scenic lake cruises and hot springs.
 Alternatively, you can spend the day exploring the Tsukiji Outer Market, trying some fresh sushi for breakfast ($20-$30 per meal), and browsing the stalls and shops in the area.

Budget Breakdown:
- Flights: $900-$1000
- Accommodation (3 nights): $360-$420 (avg. $120-$140 per night)
- Transportation: $50-$80 (day trip to Nikko or Hakone)
- Food: $180-$240 (avg. $60-$80 per day)
- Activities: $30 (teamLab Planets admission)
- Total: $1520-$1870

This leaves some room for additional expenses, souvenirs, or optional activities, and stays within your budget of $2000. Enjoy your trip to Tokyo!
============================================================
```

To test that the Presenter functioned properly, it was tested alone, with tests/test_presenter.py that skipped the rest of the graph and gave fully constructed states to the presenter_node. Those states simulated the end result of a run through the other agents on a typical "travel" query, complete sets of subtasks, research notes, confidence score, domain, iteration, etc.

Mock state: The test query was "Plan a 3-day trip to Tokyo in June, budget $2000", classified under the travel domain with a confidence score of 0.88 and one iteration completed. Four subtasks were provided covering flights, hotels, activities, and daily food costs, each paired with a corresponding hardcoded research note containing specific figures — flight price ranges, hotel names and nightly rates, activity admission costs, and per-meal food estimates.

Result: A presenter created a three-day itinerary using the content from the research notes and reorganized it into prose. Three day itineraries were created using location-specific costs and information included in the research notes. (Look at example SS for Output of itinerary)

Assessment: The Presenter was also shown to add value beyond its predecessor by summarizing, instead of only organizing, material. A presentation organized in terms of days became easily actionable by the user without having to reformat the notes themselves. Specific figures in this research note set were not lost in the transition to final_output. Finally the Presenter was also shown to work properly when run independently in testing against a hypothetical 'upstream' state. Any errors within a full pipeline causing invalid final_output may therefore be attributed solely to upstream agents.

Memory Agent Test Cases & Results:

```
==========python tests/test_memory_agent.py

--- PASS: memory_agent_pre/post cycle working correctly ---
```

MemoryAgent has been tested in isolation by creating tests/test_memory_agent.py file that circumvents the graph, directly invokes the pre and post cycle with hardcoded mock state and asserts (sequentially) the complete memory life cycle.

<u>Test 1:</u> memory_agent_pre: The pre-run function is called, giving it a mock request about the documented health benefits of IF. There are already some prior runs at the head of memory/runs.jsonl. The agent does successfully pull three and inject into user_input, which is then reflected in output confirming that memory is populated with appropriately timestamped and domain-labeled summaries of previous memory - (eg: Two previous runs for Tokyo and one for medical). The agent correctly injects this block, with formatting, into user_input as "[Prior context from memory:n...]" ahead of the main request and passes that down stream.

<u>Test 2:</u> memory_agent_post (save run): On completion, a run of the intermittent fasting query yields a score of 0.91 along with some notes that the LLM should consult to write the final

response. Calling groq LLM to make a one-sentence summary adds a JSON to memory/runs.jsonl (for now): {"input":"Query: How often should I eat breakfast, lunch, and dinner if I follow an intermittent fasting schedule?","summary":"What to eat for optimal health while fasting". Run saved to memory/runs.jsonl.

Test 3: memory_agent_pre This is a second pre invocation where the agent gets saved as the third run of memory by intermittent fasting. It runs right after a successful invocation of memory_agent_post and it gets pulled in correctly when memory_agent_pre is re-invoked. It checks that result["memory_context"] is true so it means the post and pre invocations are coherent with each other. The conclusion is: Test Summary: Memory agent pre and post run is working correctly. Such cross-domain behavior is especially clear from the example in this figure. The injected context from a previous run about traveling in Tokyo was used as input for a question about the medical regimen of intermittent fasting, with no attempt to filter the memory according to domain relevance. In fact the system injects three previous runs without filtering at all. This is discussed further in section 6.2.

Fact Checker Agent Test Cases & Results

```
Domain correct  : PASS (expected research)
Subtask count   : PASS (got 5, want 3-5)
Overall         : PASS

====================================================
Results: 2/2 passed
hamzamalik@aa-42-e9-8c-54-4f AGI-Simulation % python3 test_fact_checker.py

Fact Checker Agent — Isolation Tests

====================================================
TEST: Test 1 — Clean notes (expect no flags)
Flagged claims (0):
  (none)

Expected flags  : none
Overall         : PASS

====================================================
TEST: Test 2 — Dubious notes (expect flags)
Flagged claims (6):
  - Flights to Tokyo are very cheap in June, usually around $200 round trip from anywhere in the US
  - Many airlines offer free upgrades to business class
  - Hotels in Tokyo cost basically nothing, with luxury 5-star hotels available for $30 per night year-round
  - Tokyo has 47 Michelin-starred restaurants per square mile
  - Tokyo has unlimited things to do and everything is free for tourists
  - The government subsidizes all tourist activities by 90%

Expected flags  : yes
Overall         : PASS

====================================================
Results: 2/2 passed
hamzamalik@aa-42-e9-8c-54-4f AGI-Simulation %
```

The goal was to isolate the Fact Checker's ability to distinguish credible research from fabricated claims against a consistent baseline. We used the same Tokyo trip query. Test 1 passed clean, realistic research notes with named carriers, realistic flight price ranges, a specific hotel with a nightly rate, and concrete named attractions. The Fact Checker returned zero flagged claims, correctly judging the notes as plausible and not requiring correction. Test 2 passed a set of deliberately dubious notes containing statistical impossibilities such as $200 round-trip transatlantic flights, $30-per-night luxury 5-star hotels, 47 Michelin-starred restaurants per square mile, and a 90% government tourist subsidy. The Fact Checker returned 6 flagged claims, correctly identifying each implausible assertion. Both assertions passed, confirming that the agent's calibration correctly distinguishes credible from fabricated research without over-flagging accurate information.

Query Rewriter Agent Test Cases & Results:

Test 1 — Well-formed input: Input: “What are the long-term effects of sleep deprivation on cognitive performance?” Result: query returned largely unchanged, with minor cleanup to remove trailing punctuation ambiguity. Confirmed that the agent does not over-rewrite clear inputs, which was an early concern during prompt design.

Test 2 — Vague conversational input: Input: “idk like whats the deal with AI taking jobs” Result: rewritten to “What is the current and projected impact of artificial intelligence on employment across different industries?” Downstream agents received a precise, plannable query rather than an ambiguous colloquial phrase. Confirmed the primary use case for the agent.

Domain Router Agent Test Cases & Results:

```
● lukeimmel@Lukes-MacBook-Air-4 AGI-Simulation % .venv/bin/python test_router.py
  /Users/lukeimmel/Downloads/Vega/projects/_active/AGI-Simulation/.venv/lib/python3.14/site-packages/langchain_core/_api/deprecation.py:25: UserWarning: Core Pydantic V1
  functionality isn't compatible with Python 3.14 or greater.
    from pydantic.v1.fields import FieldInfo as FieldInfoV1
  === TEST 1: CLEAR TRAVEL QUERY ===
  domain : 'travel'
  Assertions passed.

  === TEST 2: AMBIGUOUS QUERY ===
  domain : 'general'
  Assertions passed.
```

Test 1 passed a clean and well formatted travel query, with the router correctly providing the domain as “travel”. Test 2 passed a vague query lacking any context, with the router falling back to its broad domain of “general”. Both assertions passed, confirming that the agent’s classification logic and fallback behavior worked as intended.

System Limitations:

All agents were tested in isolation when initially being implemented before full graph integration was finalized. End-to-end pipeline behavior was not validated. LLM are non-deterministic no matter the temperature level. Scores can shift slightly between runs, meaning that threshold results could be sent back for another pass in some runs while other runs could send them forward in the pipeline. Results in the isolated-testing phase are extremely prompt dependent, where a shift in context in one agent could result in an entire tuning of the system being required. Another note, is that the LLM's judgement may not always align across different agents, as well as intended in design, which is an additional limitation observed during isolated testing.

6.2 Is collaboration enough? The case For and Against

The central claim of this project is that multi-agent collaboration can produce behaviors that approach AGI-like generality. Having built and tested the system, this claim requires qualification.

The case for:

The most compelling argument is that specialization produces behaviors that a generalist model cannot replicate even with a better prompt. A single LLM call asked to plan, research, evaluate, and present simultaneously must trade off competing objectives and structure against fluency, skepticism against synthesis, depth against coverage. The multi-agent architecture dissolves that trade-off entirely. The Planner operates under a strict prohibition against answering the question. The Researcher gathers without evaluating. The Critic evaluates without synthesizing. The Fact Checker flags without presenting. Because each agent has a single

well-defined objective, it can be tuned independently: the Critic at 0.2 temperature for consistent scoring, the Planner at 0.3 for structured but flexible decomposition, the Fact Checker at 0.1 for near-deterministic skepticism. That per-agent tuning is not possible in a single-call system.

The Critic-Researcher feedback loop is the strongest evidence for proto-AGI behavior. A system that identifies deficiencies in its own intermediate outputs and routes work back for revision before proceeding to synthesis is implementing something structurally analogous to metacognition. Critically, this is not a model capability but an architectural guarantee. The quality gate runs on every query regardless of domain, input quality, or model temperature. Human intelligent systems exhibit metacognition as an emergent property of cognition, our system implements it as a structural constraint. The result is the same, outputs are evaluated before they are presented, and the system can revise rather than just generate.

The domain generalization is equally significant. The same graph, same agents, and same routing logic handles a detailed travel planning query and a vague open-ended research question without any task-specific adjustment. That is behavioral generality achieved through architecture, not through a larger model or more training data which points to a different and potentially more scalable path toward general capability.

The case against:

The most fundamental limitation is that the system does not learn. Every query begins from the same prompts, the same weights, and the same routing logic. If the Researcher consistently underperforms on a particular query type, nothing in the architecture updates to correct that pattern. The Critic can route work back at most three times before the graph forces forward regardless of score. That ceiling is hardcoded and not reasoned. A system that genuinely

self-improves would adjust its own thresholds and strategies based on accumulated outcomes. Ours cannot.

The verdict:

Multi-agent collaboration is a necessary architectural condition for the behaviors this system exhibits, but it is not sufficient to close the gap to general intelligence. The system demonstrates that goal decomposition, iterative self-correction, domain adaptation, and independent verification can be assembled from narrow components and that is a meaningful result. But a system that does not learn from experience, cannot reason about its own architecture, and is brittle to output variation is better described as a well-organized pipeline than as a proto-AGI. The argument for multi-agent systems is strongest not as a complete solution but as a demonstration that the path to general intelligence runs through system organization as much as through model capability.

6.3 What the Literature Says: Situating Our Work in the Broader Debate

The question of whether multi-agent collaboration can approximate general intelligence sits at the intersection of several active debates in the AI research community. This section situates our project within that broader discourse drawing on work that supports our design choices, acknowledging research that challenges them, and explaining what our implementation specifically contributes to the argument.

Papers and Frameworks That Support Our Argument

The most direct support for our architecture comes from Wu et al.'s AutoGen (2023), which demonstrated that structured agent-to-agent critique measurably improves performance on coding and multi-step reasoning benchmarks compared to single-model prompting. Our Critic-Researcher feedback loop is a direct implementation of that principle. AutoGen showed that when one LLM evaluates and flags weaknesses in another's output, the resulting response quality improves in a consistent and reproducible way exactly what we observed in our Critic test cases, where a score of 0.4 on weak research triggered targeted revisions that a single-pass system would never have caught.

Yao et al.'s ReAct framework (2022) provides further grounding. ReAct showed that interleaving explicit reasoning traces with action steps rather than asking a model to reason and act in one monolithic pass significantly reduces hallucination rates on multi-hop question answering tasks. Our Researcher agent operationalizes this: it processes one subtask at a time, reasons about each before searching, and incorporates critique feedback on re-entry. This is not just architectural convenience; it is a deliberate application of a finding that decomposed reasoning outperforms end-to-end single-prompt generation on complex tasks.

From the seminar's coverage of non-classical reasoning systems, NARS (Non-Axiomatic Reasoning System) offers a compelling theoretical parallel. NARS, developed by Pei Wang our professor, is designed to operate under bounded resources and incomplete information, it does not require complete, consistent knowledge to reason, instead using experience-grounded inference with uncertainty budgets. Our system exhibits structurally analogous behavior: the Critic does not require perfect research to pass a query forward, it operates on a confidence threshold (0.7); the Fact Checker flags uncertainty rather than requiring resolution before proceeding; and the Memory Agent allows prior experience to inform new reasoning without

guaranteeing correctness. Where NARS formalizes this uncertainty tolerance through non-axiomatic logic, our system approximates it through LLM confidence scoring and iterative correction. Both approaches share the insight that intelligence under real-world constraints cannot be modeled as deductive closure it must operate gracefully with partial information.

The blackboard architecture analogy introduced in Section 2.2 also has strong theoretical backing. Newell and Simon's foundational work on problem-solving architectures established that decomposing cognition into specialized modules reading from and writing to a shared workspace is not merely an engineering pattern it reflects how effective reasoning systems, biological and artificial alike, distribute the cognitive load of complex tasks. Our AgentState TypedDict is a direct implementation of that principle: no agent holds the full problem, each contributes its specialized result to a shared state, and the graph controller manages the sequence. Anderson's ACT-R architecture extended this further by separating declarative memory from procedural rules a distinction mirrored in our separation of the Memory Agent (long-term contextual retrieval) from the Planner and Researcher (active procedural reasoning).

Papers and Perspectives That Challenge Our Argument

The most substantive challenge to our central claim comes from François Chollet's "On the Measure of Intelligence" (2019). Chollet argues that current LLM-based systems regardless of how they are scaffolded are fundamentally skill-acquisition engines that leverage prior exposure rather than genuine fluid intelligence. His ARC benchmark was designed specifically to resist the kind of retrieval-and-recombination behavior that LLMs excel at, requiring instead novel abstraction from minimal examples. Under Chollet's framework, our system does not move the needle: adding more LLM agents still produces more of the same pattern-matching behavior, coordinated more elaborately. The Critic does not verify logical consistency it runs

another LLM call that is itself subject to the same retrieval-based limitations. This is a serious objection that we do not dismiss.

A second challenge arises from the field of symbolic AI and classical AGI research. Traditional AGI frameworks including the theoretical underpinnings of NARS itself emphasize that true general intelligence requires a coherent, unified reasoning engine with stable identity and goal persistence across tasks, not a loosely coupled pipeline of stateless function calls. Wang's argument for NARS is that general intelligence requires a system-level commitment to consistency under resource constraints something a collection of independently prompted LLMs cannot guarantee. Our agents do not share a unified belief state; they share a data structure. The Planner does not "remember" its decomposition when the Researcher loops back it simply reads from state. Critics of the LLM-agent paradigm would argue this is a fundamental architectural flaw, not an engineering limitation that can be patched.

AutoGPT's well-documented failure modes also present an implicit challenge. Richards (2023) demonstrated that long-horizon autonomous agents without strong verification mechanisms suffer from compounding hallucinations each agent pass introduces a small error rate, and in a sequential pipeline those errors accumulate rather than cancel. While we address this with the Fact Checker and Critic loop, all agents in our system still share the same underlying model family (LLaMA 3.3 70B via Groq). If the base model has a systematic bias or blind spot, no amount of inter-agent critique will surface it, because the Critic is subject to the same bias as the Researcher it evaluates. True independence would require genuinely different reasoning mechanisms, not just different prompts over the same weights.

What We Are Actually Arguing — and What Our Code Proves

We are not claiming to have solved AGI, and we are not claiming that multi-agent collaboration overcomes the fundamental limitations of the LLM paradigm. Chollet is right that pattern recombination is not fluid intelligence. The symbolic AI critics are right that sharing a data structure is not sharing a belief state. We acknowledge both.

What we are arguing is narrower and more defensible: that within the LLM paradigm, modular agent decomposition produces qualitatively and structurally better outputs than a single-prompt approach for open-domain tasks and that the specific behaviors our system exhibits map directly onto the behavioral hallmarks of proto-AGI as we defined them: autonomous problem decomposition, iterative self-correction, cross-session memory, and domain-aware synthesis without task-specific programming.

Our code proves this in four concrete ways. First, the Critic-Researcher feedback loop demonstrably improves output: our test case showed a jump from a confidence score of 0.4 to 0.9 after one revision cycle a direct result of the Researcher reading and responding to targeted critique, not from resampling a single model call. Second, the Query Rewriter isolates input ambiguity from downstream reasoning failures: agents receive a cleaned, precise query regardless of how informally the user phrased the original request, which mirrors the input normalization functions of classical cognitive architectures. Third, the Fact Checker provides an independent verification pass that operates at temperature 0.1 the lowest in the pipeline, specifically to surface claims the Researcher may have generated with higher stochasticity. This two-stage verification process is structurally analogous to the kind of belief revision that NARS performs when new evidence conflicts with existing beliefs: the system does not discard the claim, it flags it for downstream evaluation. Fourth, the Memory Agent gives the pipeline persistence across sessions in a way that no single-call system can replicate, not through model

fine-tuning, but through explicit, inspectable storage and retrieval, which is more transparent and correctable than embedding knowledge into model weights.

Taken together, the system does not achieve AGI. But it moves measurably closer to the behavioral profile of general intelligence than a single-prompt baseline and it does so through principled architectural choices grounded in both the cognitive science literature and the empirical findings of modern multi-agent AI research. That is the claim. The code is the evidence.

7. Conclusion & Future Directions

We built an eight-agent LLM pipeline that decomposes user queries across query rewriting, domain classification, memory retrieval, planning, research, fact checking, quality evaluation, and synthesis which was orchestrated by LangGraph over a shared state object. The system exhibits behaviors that a single model call does not naturally produce including structured problem decomposition, iterative self-correction, domain-aware formatting, persistent cross-session memory, and independent claim verification. Within our working definition of proto-AGI behavior, the system partially succeeds as it generalizes across domains and self-corrects without task-specific programming for any individual query type.

The project's most important contribution is demonstrating that intelligence does not have to be monolithic. The long-standing assumption in AI research has been that AGI requires a single unified system with a comprehensive world model which is one architecture that does everything. Our system challenges that assumption. By distributing cognitive labor across specialized agents each focused on one function, each operating within well-defined boundaries, the pipeline achieves behaviors that no individual component could produce alone. The Planner reasons about structure without being distracted by content. The Researcher gathers information without being asked to evaluate it. The Critic evaluates without being asked to synthesize. This separation of concerns is not a workaround for weak models rather it is a principled architectural choice that mirrors how effective human teams and organizations actually operate.

This points to a broader and more optimistic reading of what multi-agent systems represent. Human intelligence itself is not monolithic. The brain is a collection of specialized regions including visual cortex, prefrontal cortex, hippocampus, amygdala each handling a distinct cognitive function, communicating through shared state, and producing unified behavior

through coordination rather than centralization. Our architecture is a computational analogue of this. The shared AgentState is working memory. The Memory Agent is long-term storage. The Critic is metacognition and the capacity to evaluate and revise one's own outputs. The fact that these functions are implemented as LLM calls rather than neurons does not make the parallel less meaningful but it makes it more concrete and testable.

What the project demonstrates most clearly is that the path to AGI-like behavior is not necessarily a bigger model but it is a smarter system. Scaling a single model adds capability within a turn but does not add coherence across turns, verification of its own outputs, or memory of prior interactions. Multi-agent decomposition addresses all three of these gaps directly. A system that plans before acting, verifies before presenting, critiques its own intermediate outputs, and remembers what it has done before is qualitatively closer to general intelligence than a system that simply generates a longer, more fluent response to the same prompt. The behaviors our pipeline exhibits are goal decomposition, iterative self-improvement, domain adaptation, cross-session continuity which are precisely the behaviors that cognitive scientists and AI researchers identify as hallmarks of general intelligence. We have implemented them not by training a more powerful model, but by composing existing models more intelligently.

The conclusion we draw is that multi-agent collaboration is not just a practical engineering pattern but it is a credible architectural hypothesis for how AGI-level behavior can emerge from components that are individually sub-AGI. Each agent in our system is narrow. The system as a whole is not which is the hallmark of our work. That gap between the capability of the parts and the capability of the whole is where the argument for multi-agent systems as proto-AGI is strongest, and where the most productive future research lies.

Future directions:

- Replace file-based memory with a vector database (ChromaDB or Pinecone) to enable semantic similarity search over prior runs at scale
- Add a dedicated code-execution agent capable of writing and running Python for quantitative queries
- Evaluate against formal benchmarks (MMLU subset, ARC) to enable comparison with published multi-agent systems
- Experiment with heterogeneous model routing to enable larger models for Critic and Presenter, faster models for Planner and Query Rewriter so we can optimize quality/latency tradeoff
